

Confounding variable correction and outlier expression analysis

Eric Klee, PhD

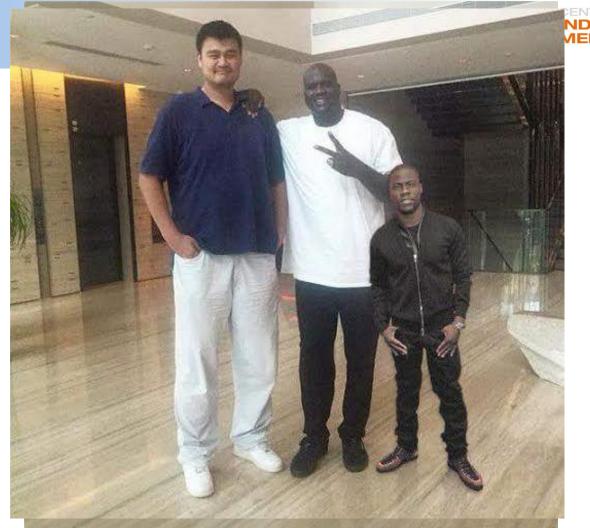

Confounding variables

- We sample a population many times and find the following data
- A 5' tall man is unusually short, but if we did not factor in sex then we would not see 5' tall adult as an outlier
- A 5' male peds patient not an outlier so age also confounder

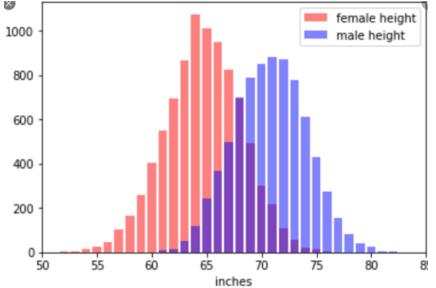

NDIVIDUALIZED MEDICINE *# W

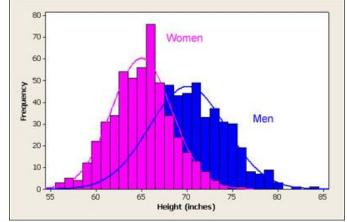

- Yao Ming is a male with 90" height
- Outlier detection has the goal of seeing this example and flagging it as an outlier or anomaly since *it is unlikely* within the population
- There are many methods for quantitatively deciding what is "unlikely" but we will discuss the broad class of methods based on statistical hypothesis tests/p-values

- First define a model, for example a separate bell curve for men and women
- Collect "normal" data and fit models to the data
 - "normal" depends on scientific question; e.g., outlier in NBA versus general population
- Calculate p-values
- Conclude outlier when p-value sufficiently small

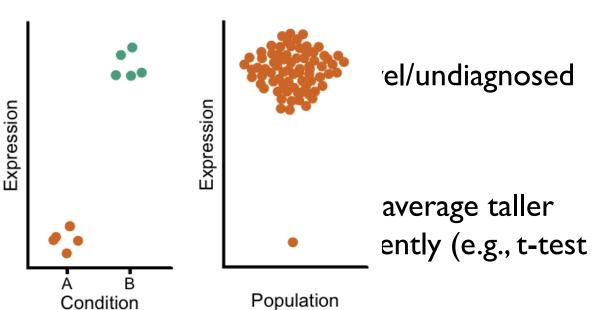

Traditional RNA-seq differential analysis

Rather than outlier
group-wise comparient
– Normal versus c

Experiment scheme

Differential expression analysis (DESeq2/edgeR) Outlier detection (OUTRIDER) l test is a

- Lung versus brai
- Requires "replicates disease
- Not an individual-le
- This is more akin tc than women and the or linear models)

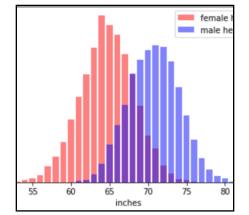

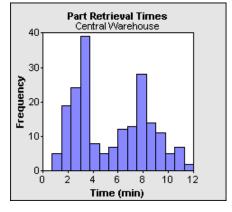

- Null: Yao Ming's 90 inch height was randomly selected from population of heights
- Suppose we estimate from data the average male is 70 inches and the standard deviation is 4 inches
- P-value for Yao Ming's height asks: "what is the probability that someone 90 inches *or taller* is randomly selected from the population"
 - Here we can calculate this as: $zscore = (90-70)/4 = 5 \rightarrow p$ -value = 0.00001
- Interpretation: it is highly unlikely that I randomly selected Yao Ming by chance from the population of heights
 - This is true. I specifically chose him due to his notoriously large height, and so outlier analysis has correctly identified an anomaly

Not all distributions are Gaussian

- The aforementioned procedure is general, but a good model should match the data generation process
- Normal distribution is good for heights but not the below graph
 - Note in the case of heights the situation was actually similar if we didn't account for sex
 - Height only looked Gaussian for each sex separately
- Z-scores sometimes used instead of p-value; incorrect unless Gaussian

- RNA extracted from the cells and sequenced
- Each sequencing read can be mapped (not always uniquely) to a given transcript/gene
- We extract counts of reads coming from each gene
- Counts need context and are not useful in isolation
 - Long genes have more RNA-bases per transcript expressed
 - Samples sequenced to higher depths will have more total counts for technical and not biological reasons
- Models for RNA counts need to account for both

Over-simplified view: just use TPM

Gene Name	Rep1 Counts	Rep2 Counts	Rep3 Counts
A (2kb)	10	12	30
B (4kb)	20	25	60
C (1kb)	5	8	15
D (10kb)	0	0	1
Total reads:	35	45	106
Tens of reads:	3.5	4.5	10.6

VIDUALIZED

MEDICINE

MAYO CLINIC

First normalize by gene length

Original data:

Gene Name	Rep1 Counts	Rep2 Counts	Rep3 Counts
A (2kb)	10	12	30
B (4kb)	20	25	60
C (1kb)	5	8	15
D (10kb)	0	0	1

INDIVIDUALIZED

* # H

MEDICINE

RPK – scaled by gene length:

Gene Name 🤇	Rep1 RPK	Rep2 RPK	Rep3 RPK
A (2kb)	5	6	15
B (4kb)	5	6.25	15
C (1kb)	5	8	15
D (10kb)	0	0	0.1

Now normalize by sequencing depth

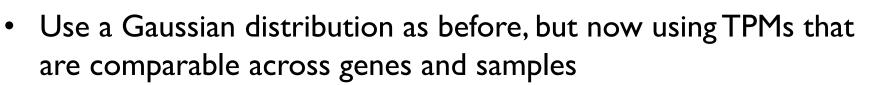

Gene Name	Rep1 RPK	Rep2 RPK	Rep3 RPK
A (2kb)	5	6	15
B (4kb)	5	6.25	15
C (1kb)	5	8	15
D (10kb)	0	0	0.1
Total RPK:	15	20.25	45.1
Tens of RPK:	1.5	2.025	4.51

INDIVIDUALIZED

MEDICINE

Gene Name	Rep1 TPM	Rep2 TPM	Rep3 TPM
A (2kb)	3.33	2.96	3.326
B (4kb)	3.33	3.09	3.326
C (1kb)	3.33	3.95	3.326
D (10kb)	0	0	0.02

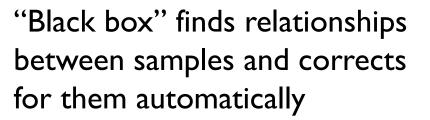

- Most sophisticated RNA-seq analysis avoid this route and model the counts directly (often with negative binomial distribution) while accounting for gene length and sequencing depth but idea is similar
- Once you model your "normal" cohort, just do outlier detection via p-values as before
 - Trick in rare disease is to use patients as "normal" cohort

MAYO CLINIC

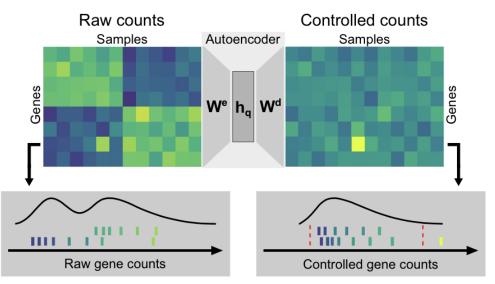

- Variables that are not of interest that affect your variable of interest
 - sex, age, smoking status, technical artifacts, cell admixture in whole blood, etc
- If your "normal" population was mostly males and you measured an average female's height you might incorrectly label them an outlier
- One option is directly accounting for them as we did with sex in heights (e.g., PEER package)
 - Pros: intuitive model we control and interpret
 - Cons: requires much more data, and corresponding meta data (i.e., sex labels)

Autoencoder

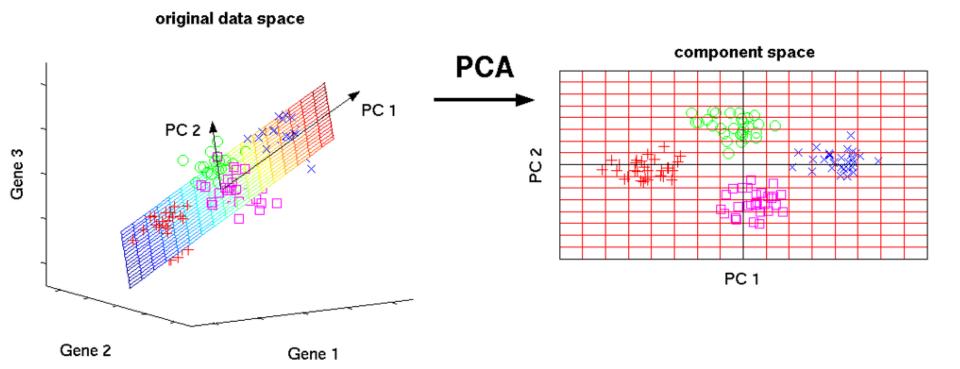

- Pros: no meta data needed, less samples needed, accounts for hidden confounders
- Cons: not easily interpretable output...need to "trust" the black-box

IZED

- 9 year old male, non-consanguineous family
- Mild global developmental delay
- General Convulsive Intractable Epilepsy
- Nevus sebaceous
- Constipation due to colonic dysmotility
- Outside diagnosis of mitochondrial disorder

Case summary

CENTER FOR INDIVIDUALIZED MEDICINE

- OUTRIDER:
 - p-value = IE-7
 - zScore = -5.4
 - 12fc = -0.69
- Gene's top CADD variant is case solving variant
- Nonsense variant p.Glu61*, consistent with the near complete allelic loss of expression

Q-Q plot for gene: CSNK2B

Slides curtesy of Garrett Jenkinson

OUTRIDER

We assume that the count k_{ij} of gene j = 1, ..., p in sample i = 1, ..., n follows a NB distribution with gene-specific dispersion parameter θ_j and expected value c_{ij} :

$$P(k_{ij}) = \text{NB}(k_{ij} \mid \mu_{ij} = c_{ij}, \theta_j).$$
 (Equation 1)

The used parameterization of the NB distribution can be found in the Supplemental Material and Methods. We limited the parameter range for θ_i to the interval [0.01, 1000]. The lower limit prevents convergence issues for genes with unusual high dispersion (θ_i close to zero), and the upper limit is used to avoid overfitting. The expected count c_{ij} is the product of the sample-specific size factor s_i and the exponential of the factor y_{ij} :

$$c_{ij} = s_i \cdot \exp(y_{ij})$$
 (Equation 2)

The size factors s_i capture variations in sequencing depth; they are robustly estimated as the median of the ratios of the gene read counts to their geometric means as implemented in DESeq.²⁴ The factors y_{ij} capture covariations across genes. They (Equation 3)

 $\mathbf{h}_{i} = \widetilde{\mathbf{x}}_{i} \mathbf{W}_{e}, \qquad (\text{Equation 4})$

MEDICINE

NDIVIDUALIZED

where the $p \times q$ matrix \mathbf{W}_e is the encoding matrix, the $q \times p$ matrix \mathbf{W}_d is the decoding matrix, the *q*-vector \mathbf{h}_i is the encoded representation, and the *p*-vector \mathbf{b} is a bias term. Having a decoding matrix that is not the transpose of the encoding matrix, unlike for principal-component analysis (PCA), turned out to be important, most likely because the property that the matrix inverse equals the matrix transpose does not generalize to the NB loss function. The input vector to the autoencoder \mathbf{x}_i is computed as follows:

$$\tilde{x}_{ij} = x_{ij} - \overline{x_j}$$
, where (Equation 5)

$$x_{ij} = \log\left(\frac{k_{ij}+1}{s_i}\right),$$
 (Equation 6)

where we add 1 to prevent computing the logarithm of 0, we divide by the size factor to control for sequencing depth, and we center gene-wise by subtracting the mean $\overline{x_j}$. In the following, we call the combination of Equations 2–6 the autoencoder or, in short, $c_{ij} = AE(k_{ij})$.

2.2 Fitting of the parameters

All notations are introduced in the Materials and Methods section.

Negative Binomial model

We use the following parameterization of the negative binomial distribution:

$$P(k|\mu,\theta) = \frac{\Gamma(k+\theta)}{\Gamma(\theta)k!} \left(\frac{\mu}{\mu+\theta}\right)^k \left(\frac{\theta}{\mu+\theta}\right)^{\theta}$$

where the variance of the distribution is given by:

$$Var = \mu + rac{\mu^2}{ heta}$$

Negative log-likelihood

The negative log-likelihood nll of the model is given by:

$$\begin{aligned} \text{nll} &= -\sum_{ij} k_{ij} \log \left(\mu_{ij} \right) - \sum_{ij} \theta_j \log \left(\theta_j \right) + \sum_{ij} (k_{ij} + \theta_j) \log \left(\mu_{ij} + \theta_j \right) \\ &- \sum_{ij} \log \left(\Gamma(k_{ij} + \theta_j) \right) + \sum_{ij} \log \left(\Gamma(\theta_j) k_{ij} \right) \end{aligned}$$

For the optimization of the model only the first and third term of the nll need to be considered, as all other terms are independent of \mathbf{W}_e and \mathbf{W}_d , yielding the following truncated form of the negative log likelihood:

$$\operatorname{nll}_{\mathbf{W}} = -\sum_{ij} \left[k_{ij} \log \left(\mu_{ij} \right) - \left(k_{ij} + \theta_j \right) \log \left(\mu_{ij} + \theta_j \right) \right]$$
(1)

We use L-BFGS to fit the autoencoder model as described in Methods. We implemented the following gradients.

The expectations μ_{ij} are modeled by:

$$\mu_{ij} = s_i e^{y_{ij}}$$

Hence, nll_W can be rewritten as:

$$\operatorname{nll}_{\mathbf{W}} = -\sum_{ij} \left[k_{ij} \log(s_i) + y_{ij} - (k_{ij} + \theta_j) \cdot \left(\log(s_i) + y_{ij} + \log\left(1 + \frac{\theta_j}{s_i \cdot e^{y_{ij}}}\right) \right) \right]$$

In the following the y_{ij} are the elements of the Y defined as:

$$\mathbf{Y} = \mathbf{X} \mathbf{W}_e \mathbf{W}_d^T + \mathbf{b},\tag{2}$$

where the element (i, j) of the matrix **X** is given by: $\log\left(\frac{k_{ij}+1}{s_i}\right) - \bar{x}_j$.
